

A Flexible Two-Dimensional Mortality Model for Use in Indirect Estimation

John Wilmoth*, Vladimir Canudas-Romo†, Sarah Zureick*, Mie Inoue**, and Cheryl Sawyer††

February 2009

ABSTRACT

Objective. Mortality estimates for many populations must be derived using model life tables, which describe typical age patterns of human mortality. We propose a new system of model life tables as a means of improving both the quality and the transparency of such estimates.

Methods. We describe a flexible two-dimensional model of the age pattern of mortality and fit the model (separately by sex) to a collection of 616 period life tables from the Human Mortality Database (www.mortality.org). The fitted model can be used to estimate full life tables given one or two pieces of information: for example, child mortality only (${}_5q_0$), or child mortality and adult mortality (${}_5q_0$ and ${}_{45}q_{15}$). Using empirical life tables from a variety of sources, we compare the performance of new and old methods by computing standard deviations of estimation errors for three key mortality indicators (e_0 , IMR , and ${}_{45}q_{15}$).

Findings. The new model easily outperforms the Coale-Demeny and UN model life tables. Estimation errors are similar to those produced by the modified Brass logit procedure. If desired, the model can be applied in a flexible manner to incorporate non-quantitative information about the age pattern of mortality (similar to the use of regional families in the Coale-Demeny system).

Conclusion. In addition to generally providing smaller estimation errors, the new method offers other advantages over existing techniques. The proposed model is better suited to the practical needs of mortality estimation, because the two input parameters are both continuous yet the second one is optional. Also, since model parameters are closely related to measures of child and adult mortality, the link between data and estimates is more transparent.

Introduction

Life expectancy and other summary measures of mortality or longevity are key indicators of the health and wellbeing of a population. The Human Development Index of the United Nations, for example, lists life expectancy at birth as the first of its three components.¹

By definition, a population's life expectancy at birth is the average age at death that would be observed among a (hypothetical) cohort of individuals if their lifetime mortality experience matched exactly the risks of dying (as reflected in age-specific death rates) observed for the population during a given year or time period. Thus, the starting point for deriving the value of life expectancy at birth is a complete set of age-specific mortality rates; using this information, it is possible to calculate life expectancy at birth and other summary indicators of mortality or longevity. Typically, all of these calculations are made separately by sex.

Currently, three organizations produce regularly-updated estimates of life expectancy at birth by sex for all (or nearly all) national populations: the United Nations Population Division, the World Health Organization, and the U.S. Census Bureau. This task is greatly complicated by the fact that different data sources and estimation methods must be employed for different groups of countries. For wealthy countries with complete and reliable systems for collecting population statistics, age-specific death rates are derived directly from administrative data (by dividing the recorded number of deaths by an appropriate measure of population size).

For most of the world's population, however, the usual administrative data sources (death registration and census information) are inadequate as a means of deriving reliable estimates of age-specific mortality rates and, thus, life expectancy or other synthetic measures. For these populations, mortality estimates are derived using model life tables, which describe typical age patterns of human mortality. Using such models, it is possible to estimate death rates for all ages given limited age-specific data.

For example, in many countries it has been possible to obtain empirical evidence about levels of child mortality using survey data and other instruments, even though there is little or no reliable data on adult mortality. For other countries there may also be some means of estimating mortality for young and middle-aged adults, but no reliable information at older ages. In these and other cases, model life tables exploit the strong positive correlations between mortality levels at different ages (as observed in a large body of historical and cross-cultural data) as a means of predicting mortality levels for all ages using the limited information available.

In this paper we propose a new model of age-specific mortality, which we use to develop a new system of model life tables. In addition to producing smaller estimation errors in most cases, this model offers several significant advantages compared to earlier approaches, including its greater flexibility and intuitive appeal. We believe that the new model will be very useful as part of ongoing efforts to improve both the quality and the transparency of global mortality estimates.

We begin the discussion with a brief review of the literature on model life tables, followed by an analysis of the data sources available for deriving and testing such models. We then present the two-dimensional mortality model that we are proposing as the basis for a new system of model life tables. After fitting the model to a vast collection of historical mortality data, we illustrate how it can be used to derive a wide variety of mortality patterns by age.

¹ The other two components are education/literacy and personal income. All three components have equal weight in deriving the index, but life expectancy is typically listed first.

The model is two-dimensional in the sense that it requires two input parameters in order to produce a complete set of age-specific mortality rates. However, the second input parameter is optional in practice, yielding a flexible one- or two-dimensional model. Thus, the model can be used to estimate mortality at all ages on the basis of child mortality alone (${}_5q_0$), or using information about the mortality of both children and adults (${}_5q_0$ and ${}_{45}q_{15}$). In fact, many combinations of one or two pieces of information can be used as model inputs.

Using empirical life tables from a variety of sources, we compare the performance of new and old methods by computing standard deviations of estimation errors for three key mortality indicators (e_0 , IMR , and ${}_{45}q_{15}$). The new model easily outperforms the Coale-Demeny and UN model life tables. If desired, it is possible to incorporate non-quantitative information about the age pattern of mortality, and thus to mimic the use of regional families in these earlier model life table systems. Although estimation errors are similar to those produced by the modified Brass logit procedure, we believe that the greater transparency and flexibility of the model proposed here offer significant advantages and will facilitate further improvements in estimation methodology.

We close the paper with a discussion of some potential uses of the new model both in the area of mortality estimation and beyond.

Use of model life tables for mortality estimation

Broadly speaking, there are two major categories of models that have been used to depict the age pattern of mortality. On the one hand, there are *functional models*, which are based on fairly simple mathematical functions with a relatively small number of parameters. The most common examples are the models proposed by Gompertz and Makeham in the 19th century (containing two and three parameters, respectively). The two-parameter Weibull model (Weibull, 1951) offers an alternative to the Gompertz.

During the 20th century, different forms of the logistic model (with three or four parameters) were advocated by various authors (Perks, 1932; Beard, 1971; Thatcher *et al.*, 1998). However, functional models with two to four parameters are useful for depicting mortality at adult ages only. For a model that is capable of depicting mortality over the full age range, more parameters are needed: examples include the five-parameter Siler model (Siler, 1979) and the eight-parameter model proposed by Heligman and Pollard (1980).

On the other hand, a variety of *empirical models* have also been used for describing the age pattern of mortality. This category includes model life tables as well as the relational models proposed by Brass (1971) and others. All such models are characterized by having a much larger number of parameters compared to the functional models. However, most of the parameters in an empirical model are determined through an initial analysis of a large collection of historical data and thus become fixed in subsequent applications; after this preliminary analysis, only a small number of parameters (typically, from two to four) remain variable. These remaining parameters are sometimes referred to as the “entry parameters,” as they provide the point of entry for all subsequent applications of the empirical model.

Functional models have the virtue of simplicity and are useful for many analytical purposes. However, because empirical models are more flexible and typically provide a closer fit to observed mortality patterns over the full age range, they are better suited for the task of

estimating mortality. The model proposed here belongs to the class of empirical models. Others in this class that we have examined closely include the Coale-Demeny regional families of model life tables (Coale and Demeny, 1966, 1983), the United Nations model life tables for developing countries (United Nations, 1982), and a modified version of the Brass logit model proposed by Murray and colleagues (2003). The early model life tables proposed by Ledermann (1969) are seldom used today, but it is worth noting that their underlying structure is similar in certain ways to the model proposed here.

A system of model life tables can be used to predict the relationship between child and adult mortality. However, as shown in Figure 1, the Coale-Demeny tables do not reflect this relationship accurately, especially at low levels of mortality (see also Coale and Guo, 1989). A similar pattern is observed for the UN model life tables, as documented in the supplemental materials for this article (Wilmoth *et al.*, 2009). These results do not suggest a faulty analysis by the creators of earlier systems of model life tables, since the low levels of mortality observed in recent decades were not part of the datasets used to create those models. The bias is most severe when child mortality drops below about 50-60 per 1000. Due to the rapid decline of mortality in developing countries, a growing number of populations for which mortality estimates are derived using model life tables now have child mortality levels in this range.²

Beyond just updating the models used for mortality estimation by incorporating the full body of available data, we have also sought to develop a better underlying model. Although all model life table systems that have found wide use have had two entry parameters, a two-dimensional model may not be adequate for all purposes. At one extreme, it is clear that such a model will not describe accurately the age pattern of male mortality in times of warfare. Nevertheless, as we show by means of historical examples later in the paper, for populations affected by certain epidemics or less severe civil conflicts, a two-dimensional model appears to provide a useful approximation for the true age pattern of mortality.

It is uncertain whether the model proposed here could provide an adequate depiction of mortality in populations heavily affected by the AIDS epidemic. If not, the model life table system proposed here could be used (like earlier systems) as a means of estimating mortality from causes other than AIDS, with estimates of AIDS mortality coming from a simulation model (this is the current practice for all major data providers). This issue requires further investigation but is beyond the scope of this article.

Data from empirical life tables

For fitting the new model and testing it against alternatives, we have used life tables from several sources. Table 1 contains a summary of the four sets of life tables that were used for this study. Data from the Human Mortality Database (HMD, www.mortality.org) are described in Table 1a. This dataset contains 616 period life tables covering (mostly) five-year time intervals and represents over 65 billion person-years of exposure-to-risk, spread across parts of five continents and four centuries. All life tables in this collection were computed directly from observed deaths

² For the 2006 round of estimates from the United Nations, more than 20 countries fell into this category, including many small countries but also Indonesia, the Philippines, and Turkey.

and population counts, without adjustment except at the oldest ages.³ A convenient feature is that all data are available up to an open interval of age 110 and above.

A large collection of life tables was assembled by the World Health Organization a few years ago and was subsequently used for creating a modified form of the Brass logit model of human survival (Murray *et al.*, 2003). This data source is summarized in Table 1b. However, for both this and the following collections of life tables, we have omitted data for countries and time periods that are covered by the HMD. The non-overlapping portion of the WHO life table collection consists mostly of life tables computed directly from data on deaths and population size, which were taken (without adjustment) from the WHO mortality database (the current version of this database is available at <http://www.who.int/healthinfo/morttables/en/>). Many of these life tables are for countries of Latin America or the Caribbean. A much smaller number of tables were taken from two earlier collections of life tables: those assembled by Preston and his collaborators (Preston *et al.*, 1972), and those used for constructing the UN model life tables for developing countries (United Nations, 1982). Many of the life tables in the UN collection and were derived using some form of data adjustment and/or modeling, which were performed with the intent of correcting known or suspected errors. While many of the life tables in the Preston collection appear to be unadjusted, the accuracy of the underlying data is questionable. All data in the WHO collection are available in standard 5-year age categories up to age 85 and above.

In Table 1c we summarize a collection of 19 life tables from the INDEPTH project, which has brought together data from demographic surveillance sites located in Africa and elsewhere (INDEPTH network, 2002). In these surveillance areas, complete demographic data are collected for relatively small and well-defined populations. All except two of these tables refer to African sites; the other two refer to the Matlab areas (treatment and control) in Bangladesh. The INDEPTH life tables used here are for the time period of 1995-1999 (approximately). These are the only life tables from the INDEPTH project that have been published to date, and in principle they were computed directly from observed data without any form of adjustment.⁴

Data from the Human Life-Table Database (HLD, www.lifetable.de) are summarized in Table 1d (after removing all overlap with the HMD or the WHO collection). These life tables form a disparate collection of data from various countries and time periods. Due to the variety of data sources, the format of the data is not highly standardized. We assembled a uniform set of key mortality indicators (e_0 , ${}_1q_0$, ${}_5q_0$, ${}_{45}q_{15}$, and ${}_{20}q_{60}$) for testing the new mortality model, but those are the only data from the HLD that were used for this project. Although we have not checked all sources closely, we suspect that many of these tables were constructed using some form of data adjustment or model fitting (not only at older ages).

³ HMD data have been corrected for obvious errors in published data sources: for example, an entry of '30,000' that clearly should have been '300' (such corrections are often confirmed by marginal totals). Errors due to misreporting of age have generally not been corrected. A fitted curve following the Kannisto model (Thatcher *et al.*, 1998) assures smoothness (and a more plausible trajectory of old-age mortality in some cases), but only for the oldest ages (above age 95 approximately).

⁴ We have heard anecdotally that some estimates in the INDEPTH set of life tables were, in fact, derived using models and thus do not represent direct estimates in all cases. Although we have not obtained more detailed information on this specific point, these few cases appear to be exceptions to a general practice of direct calculation without adjustment or use of models.

Two mortality models

Here, we will consider the following two models:⁵

$$\text{Log-linear:} \quad \log(m_{xi}) = a_x + b_x h_i + v_x k_i + e_{xi}$$

$$\text{Log-quadratic:} \quad \log(m_{xi}) = a_x + b_x h_i + c_x h_i^2 + v_x k_i + e_{xi}$$

These models describe variation in log-mortality over age (x) for a given population (i). For both models, a_x , b_x , c_x , and v_x , are age-specific parameters, which can be combined in various ways to create plausible mortality curves.⁶ For a given population, the values of h and k are constant across the life span and thus determine the shape of the mortality curve for a given set of the four age-specific parameters. Lastly, e_{xi} is a random error term.

For the model life table systems derived from these models, we always define $h = \log({}_5q_0)$, where ${}_5q_0$ is the probability of dying before age 5. Thus, h serves as the first (and primary) entry parameter for the system. This formulation reflects the fact that ${}_5q_0$ is the only mortality statistic for which some empirical information is available in recent decades for almost all national populations. The second entry parameter is k , which has a typical value of zero. In fact, most empirical observations of k lie between -2 and +2, and it is rarely outside the range of -4 to +4. Thus, it is often useful for theoretical or practical reasons to set $k = 0$.

The form of the models proposed here is motivated by an empirical finding of approximate linearity in the relationship between mortality levels for various age groups, when mortality rates or probabilities of dying are expressed in a logarithmic scale. Correlation coefficients between $\log({}_n m_x)$ and $\log({}_5q_0)$ are reported in Table 2. Note that these correlations are much higher at younger ages and near zero at the oldest ages.

Building on this empirical relationship, the first portion of the log-linear model, $a_x + b_x h$, describes a linear relationship in a log-log scale.⁷ Although this log-linear relationship explains most of the variation in the data, there are two important, non-random deviations from this purely log-linear form that should be reflected in the model. First, as illustrated in Figure 2, many of the empirical relationships show a marked curvature, suggesting that a quadratic term should be added to the model.⁸ This curvature is well described by the first portion of the log-quadratic model, $a_x + b_x h + c_x h^2$, which achieves a better overall fit to the data by various measures (as illustrated below). For this reason, the remainder of this discussion will emphasize the log-quadratic model.

Second, deviations from exactly linear or quadratic relationships tend to occur simultaneously and in a similar fashion across age groups for the same population. In the models proposed here, such deviations are captured by adding another term, $v_x k$, to the model. When k differs from

⁵ The models are modifications of an earlier proposal by Wilmoth, Andreev, and Sawyer (forthcoming).

⁶ In theory, the age groups used with these models could have any width. Although x , as written here, refers to single-year age groups, actual calculations involve mostly 5-year age groups (i.e., 0, 1-4, 5-9, 10-14, ..., 105-109, 110+).

⁷ A similar log-linear relationship forms the basis of the Lee-Carter mortality model, which has been widely used for mortality forecasting (Lee and Carter, 1992).

⁸ Note that the quadratic curves in Figure 2 tend to bend upward at younger ages (except age 0) and downward at older ages

zero, this term depicts the typical pattern of co-variation across age in deviations from an exactly linear or quadratic form. Thus, a one-parameter model (when $k = 0$) is *exactly* log-linear or log-quadratic. By contrast, a two-parameter model implies an *approximate* log-linear or log-quadratic relationship.

Fitting the models to observed data

Both models have been fitted separately by sex using various methods applied to a collection of 616 sex-specific life tables from the Human Mortality Database (see Table 1). All of these life tables have the same configuration of age groups (0, 1-4, 5-9, 10-14, ..., 105-109, 110+), and almost all of them refer to 5-year time periods. The motivation for using this particular dataset will be discussed in a later section of this article.

The fitting procedure using ordinary least squares (OLS) is quite simple. It consists of fitting a series of linear or quadratic regressions of $\log({}_n m_x)$ as a function of $\log({}_5 q_0)$, in order to obtain the estimated coefficients, \hat{a}_x , \hat{b}_x , and \hat{c}_x . Each of these separate regressions results in a predicted line or curve describing the relationship between $\log({}_5 q_0)$ and $\log({}_n m_x)$ for each age group, as depicted in Figure 2 for broad age groups.⁹ In a second step, the last set of estimated coefficients, \hat{v}_x , are obtained from the first term of a singular value decomposition computed from the matrix of regression residuals. This term captures the common tendency toward positive co-variation (of unusually high or low mortality rates) for adjacent age groups, especially in the prime adult years.

Both the OLS method and our preferred fitting procedure are described fully in the Appendix of this article. A discussion of alternative means of fitting the model and a justification of our preferred method are available in a supplemental report (Wilmoth *et al.*, 2009). In short, our preferred fitting procedure involves a form of weighted least squares, in which we assign progressively less weight to observations with larger residual values. Compared to ordinary least squares, the difference in fitted values by our preferred method is negligible except for ages 15-59 among males and ages 15-29 among females. The estimated coefficients based on our preferred fitting method are reported here in Table 3 for the log-linear and log-quadratic models.

Mortality estimation using the fitted models

As an estimation tool, the models can be used to derive a full life table given either one or two pieces of information. In the first case, one assumes that the only reliable data that are available refer to child mortality, expressed in the form of ${}_5 q_0$. Lacking independent information about adult mortality, we assume that $k = 0$. In the two-parameter case, one assumes that information is also available about adult mortality, in the form of ${}_{45} q_{15}$.¹⁰ Thus, for a given set of age-specific coefficients and a known value of ${}_5 q_0$, we choose a value of k in order to reproduce the observed value of ${}_{45} q_{15}$ exactly.¹¹

⁹ Graphs similar to Figure 2 but with greater age detail are available in a supplemental report (Wilmoth *et al.*, 2009).

¹⁰ Although another summary measure of adult mortality could be used, for the present discussion we always use ${}_{45} q_{15}$.

¹¹ Calculation of k in this situation is fairly simple but requires an iterative procedure.

Using $h = \log({}_5q_0)$ and k derived in this manner, the two models can be used to estimate age-specific mortality rates across the life span by application of the following formulas:

$$\text{Log-linear:} \quad \hat{m}_x = e^{\hat{a}_x + \hat{b}_x h + \hat{v}_x k}$$

$$\text{Log-quadratic:} \quad \hat{m}_x = e^{\hat{a}_x + \hat{b}_x h + \hat{c}_x h^2 + \hat{v}_x k}$$

These rates can then be transformed into a life table, from which it is easy to derive all of the usual summary measures of mortality, including life expectancy at birth. The errors of estimation that result directly from this procedure (i.e., assuming the input values are correct) will be discussed in a later section of this article.

Age patterns of mortality implied by the models

Changes in the age pattern of mortality are illustrated in Figure 3, which shows the effect of changes in h and k on the shape of the mortality curve as a function of age for the log-quadratic model.¹² The first parameter, $h = \log({}_5q_0)$, controls the overall level of mortality. As the level moves up or down, there are progressive changes in the tilt and shape of the curve. The second parameter, k , alters the shape of the mortality curve, especially for young and middle adult ages (roughly, from the teens to the 60s). Thus, when k is greater/less than zero, adult mortality is relatively high/low given the associated value of ${}_5q_0$.

The model can be specified using various combinations of one or two pieces of information, from which we derive associated values of h and k by some computational procedure. Our computer programs permit calculation of the full model using various combinations of the following five inputs: ${}_1q_0$, ${}_5q_0$, k , ${}_{45}q_{15}$, and e_0 . Any pairing of two out these five quantities is sufficient to specify the model except the pairing of ${}_1q_0$ and ${}_5q_0$, which provides no direct information about adult mortality. Any pairing that involves k can be specified by assuming that $k = 0$; thus, in the absence of convincing evidence about relative levels of child and adult mortality (compared to historical averages), the model can be fully specified given only one of the other four inputs.

Figure 4 illustrates three of these possible pairings, for females on the left and males on the right.¹³ In each case, these graphs show changes in the age pattern of mortality as we hold one of the two quantities constant while varying the other one. For this figure only, the age patterns have been smoothed by fitting spline functions to the predicted values of death rates in 5-year age intervals; the smoothing helps to clarify the underlying shape. This exercise demonstrates that the model is capable of reproducing a wide variety of mortality curves, but also that these curves have entirely plausible shapes so long as k stays roughly within +/- 4. In particular, the following three features of these curves are consistent with a large body of cross-cultural and historical evidence:

1. A minimum occurs regularly around ages 10-11;
2. Above age 30 each curve is fairly straight (in a log scale) but with a slight S-shape; and
3. Holding k constant (see middle row panels), the “accident hump” at young adult ages is more prominent at lower levels of mortality and for men. For women, it is possible to observe a gradual transition from a “maternal mortality hump” (roughly, ages 15-45) at

¹² Age patterns produced by the log-linear model are very similar.

¹³ Similar graphs with all possible pairings are provided in a supplemental report (Wilmoth *et al.*, 2009).

the highest levels of mortality, to an attenuated male-type accident hump (roughly, ages 15-25) at lower levels.

For larger values of k (beyond ± 4 , approximately), the mortality curves tend to become distorted (see examples in Wilmoth *et al.*, 2009). For k around ± 4 , these distortions are fairly minor: they may have aesthetic but no practical importance, in the sense that they would have no noticeable effect on calculated values of major summary indicators (such as life expectancy at birth). For more extreme values of k (say, ± 8), the curves become more severely distorted. For example, with very large negative values, the accident hump tends to disappear, and the minimum value can move to much higher ages (around age 30). Because historical values of k lie in a fairly narrow range, this parameter can serve as an important plausibility check on the estimation procedure described previously.

Relationship of the models to historical evidence

Figure 5 illustrates the relationship between the two entry parameters of the log-quadratic model, ${}_5q_0$ and k , and the level of adult mortality as measured by ${}_{45}q_{15}$. Five curves trace the predicted relationship between ${}_5q_0$ and ${}_{45}q_{15}$ corresponding to k equal to $-2, -1, 0, 1, \text{ or } 2$. These curves overlaid a scatter plot of the observed values of ${}_5q_0$ and ${}_{45}q_{15}$ from the dataset that was used for estimating the model.

In order to use the fitted model as a tool for estimating a complete age pattern of mortality, we have proposed choosing k to match exactly the value of ${}_{45}q_{15}$ if the latter is available. Following this approach, the model is capable of reproducing any combination of ${}_5q_0$ and ${}_{45}q_{15}$ through an appropriate choice of k . Likewise, any combination of ${}_5q_0$ and ${}_{45}q_{15}$ implies a unique value of k . It is notable in this regard that the values of k implied by this diverse dataset (see Table 1) lie within a fairly narrow range, only rarely exceeding the interval from -2 to $+2$. However, there are three important exceptions.

First, in the left-hand portion of each graph, there is a cluster of points lying above the curve representing $k = 2$. These points correspond to certain countries of the former Soviet Union and Eastern Europe, which have experienced usually high adult mortality in recent decades, especially among men, in the wake of massive social and political changes. Second, a sole data point lies well above the same curve on the right-hand side of the graph for men only. This point corresponds to Finland during 1940-44 and reflects excess mortality among young men fighting in wars against the Soviet Union.¹⁴

Third, on the right-hand side of the graph there are a few points lying below the curve representing $k = -2$, especially for women. The data points in this area of the graph (both slightly above and below $k = -2$) correspond to countries of Southern Europe during the 1950s and early 1960s,¹⁵ and reflect a situation of unusually low adult mortality relative to child mortality (or, put differently, unusually high child mortality relative to adult mortality). As

¹⁴ In the dataset used here for estimating the models, the Finnish case of 1940-44 is the only example of a male mortality pattern that is substantially affected by war mortality. It was left in the dataset in order to emphasize this important point: for other countries with substantial war losses during the period covered by the data set, the series that we have used here reflect exclusively or primarily the mortality experience of the civilian population in times of war. The age pattern of male mortality in these situations is clearly atypical and requires a special treatment.

¹⁵ Portugal and Bulgaria are the most extreme cases.

illustrated in Figure 1, the South family of the Coale-Demeny model life table system depicted accurately the mortality experience of this region during those decades; but afterward, it has deviated from the historical record as mortality fell to lower levels in these countries.

Figure 6 shows results very similar to those in Figure 5 but broken down by smaller age groups. These graphs demonstrate that the relative impact of the k parameter on predicted levels of mortality differs for the various age groups and by sex. For both men and women, this parameter helps to distinguish between high or low levels of adult mortality (relative to child levels) throughout the age range from 15 to 59. However, in the age group of 60-79, the importance of the k parameter remains for men but diminishes substantially for women. For women at ages 60-79 and for both sexes at ages 80-99, the variability in the data vastly exceeds the variability implied by choices of k within a plausible range.

These results reflect the fact that the positive co-variation in levels of adult mortality relative to child mortality is limited to a particular age range. The variability in relative levels of mortality at older ages is not highly correlated with the variability observed at younger adult ages and is thus random variation from the perspective of the model. Moreover, the age range where the k parameter has a substantial impact on mortality estimates is somewhat narrower for women than for men. In times of social and political instability, when adults of both sexes are exposed to elevated risks of dying, this excess vulnerability tends to affect men both more intensely and over a broader age range compared to women.

Figure 7 presents six historical examples for the purpose of demonstrating the capabilities of the log-quadratic model as well as its limitations. These examples are not typical of the vast majority of historical observations; rather, they are exceptional in one manner or another. Thus, this illustration is intended to explore the limits of the model as a means of depicting historically well-documented age patterns of mortality. Each graph in Figure 7 shows observed data in comparison to estimates derived from the log-quadratic model. There are two sets of estimates, obtained by inserting observed values of either ${}_5q_0$ alone, or ${}_5q_0$ and ${}_{45}q_{15}$ together, as inputs to the model. The implied values of k are reported in the graph for each set of estimates (in the one-parameter case, $k = 0$ by definition).

The top row of Figure 7 compares the age pattern of mortality for two groups of men in England and Wales during 1940-44. On the left, the total population (including active military personnel) has an age pattern that is severely distorted compared to typical mortality curves. In this case the model is clearly incapable of mimicking the underlying pattern even with two input parameters. On the right, however, the civilian population (excluding the military population) has a highly typical age profile, with a very small implicit value of k in the two-parameter case.

Although the model may do poorly in representing the age pattern of war mortality, the other four examples in Figure 7 depict relatively extreme cases where the model performs reasonably well when both inputs are supplied. The graphs in the middle row document the excess adult mortality due to the Spanish flu (for women in Denmark) and to the Spanish civil war (for men in Spain). The graphs in the bottom row illustrate extreme cases of relatively low or high adult mortality in peacetime (for, respectively, Portuguese women in the 1960s and Russian men in recent years). In all four cases, the two-parameter version of the log-quadratic model provides an imperfect yet, for most purposes, adequate depiction of the age pattern of mortality. By contrast, the one-parameter version of the model yields rather large errors both in the shape of the age pattern and in the resulting value of life expectancy at birth.

Choice of dataset used for fitting the models

The estimated coefficients for the log-linear and log-quadratic models shown in Table 3 were derived using data drawn exclusively from the Human Mortality Database (HMD). After weighing various options, we chose to fit the models using only these data, but to test it using data from all available sources. The first choice is somewhat controversial, since the HMD dataset includes life tables for only two developing countries (Taiwan and Chile), whose mortality experience is not typical of most developing countries, and because there is only one large country (Japan) with a majority population of non-European origin. This feature of our analysis raises the question of whether the fitted model is appropriate for use in estimating the mortality patterns of developing countries.

We begin our argument by noting the choice of a dataset in this context is inherently difficult and may have no perfect solution. On the one hand, it seems very important to derive the model using accurate information about the age pattern of mortality. On the other hand, it seems equally important to derive the model using data that are representative of the full range of true mortality patterns occurring throughout the world. Since the quality of available information tends to be much lower in developing countries (in terms of the completeness and reliability of data collected through vital registration and periodic censuses), a tradeoff between the accuracy and representativeness of the data used for fitting the model is unavoidable.

The choice to fit the new model using only the HMD dataset was made for several reasons. Three of these reasons are properties of the HMD dataset itself. First, the dataset is well documented, which helps to assure that the empirical basis of the model will be, if not fully transparent, at least readily accessible. Second, to minimize transcription errors, HMD life tables are derived using data obtained directly from national statistical offices or their regular publications (not through an intermediary like the WHO); data preparation includes procedures designed to detect gross errors and other anomalies. Third, age-specific mortality rates are computed directly from official data, without major adjustment or use of fitted models except for the oldest ages. One consequence of this approach is that countries and time periods included in the HMD have in principle been filtered according to the quality of the available statistical information.

By these criteria, the additional life tables from the other large collections considered here (WHO and HLD; see Tables 1b and 1d) would be less desirable than the HMD data but not necessarily without value. Thus, our choice not to include the other life table collections when fitting the model was also motivated by certain features of those datasets that we considered less desirable. As a practical matter, the differing age formats of the various life tables presented a minor or a serious obstacle, depending on the case. In order to combine the various life table collections to enable a joint analysis, a common age format was needed. However, to avoid sacrificing the age detail available in the HMD, it was necessary to extend the age groupings of other tables so that they, too, would end with an age category of 110+. For the HLD tables, the variety of age formats would have necessitated a considerable effort in order to create tables with uniform age categories.

By contrast, the life tables of the WHO and INDEPTH collections have uniform age groupings up to age 85, and thus we were able to extend the age range to 110+ with only a modest amount

of work.¹⁶ These life tables were combined with the HMD data to produce an alternative fitting of the log-quadratic model. This exercise revealed that adding the life tables from these two collections to the HMD dataset has almost no impact on the fitted model (Wilmoth *et al.*, 2009). Moreover, the only noticeable change induced by adding the WHO and INDEPTH life tables when fitting the model was that predicted values of old-age mortality (especially above age 80) moved slightly downward. However, this change seems undesirable for two reasons. First, the impact of the additional life tables on the estimated model occurs mostly above age 80, yet the additional data points above age 85 are not observed values but rather the product of an extrapolative procedure. Second, the slight reduction in fitted values may reflect nothing more than common flaws affecting unadjusted mortality data at older ages, especially in countries with less reliable statistical systems.

Age misreporting is a well-known problem in mortality estimation, especially at older ages, where the resulting bias is always downward (Coale & Kisker, 1990; Preston *et al.*, 1999). Figure 8 is informative in this regard, as it illustrates the relationship between our preferred estimates of the log-quadratic model and data from the WHO and INDEPTH collections for ages 15-59 and 60-79. In the younger age group, the observations from the two latter datasets lie within a plausible range and demonstrate no obvious bias. In the older age groups, however, there is a clear downward bias in the observations from the WHO and INDEPTH datasets relative to the model derived using the HMD data alone. We believe that the first result is a strong confirmation of the general applicability of the model for a wide variety of human populations. At the same time, we believe that the second result is more likely due to imperfections in mortality data at older ages than to some limitation of the estimated model.

For these reasons we conclude that it is better to estimate the new model using a more restricted dataset, but to test the resulting model life table system using data from a wide variety of populations. In all cases we must keep in mind that a failed test may indicate problems with the data or with the model.

Accuracy of estimation

We evaluate the performance of the log-quadratic and log-linear models in this section along two dimensions. First, we compare the performance of the estimation procedure proposed here to methods that are currently used by various international agencies and national statistical offices. Such methods are used for creating internationally comparable mortality estimates. We are interested in whether our new method can produce more accurate estimates than existing methods. Secondly, we examine the internal and external validity of the model. We want to ensure that the estimation procedure can be applied confidently in contexts outside of the areas represented in the HMD.

We have tested the new method against three existing procedures: estimation based on the Coale-Demeny model life tables, the UN model life tables for developing countries, and the modified logit model. We use four data sets to make comparisons among the different methods: the HMD, the INDEPTH collection, and both the WHO and HLD collections excluding life tables that overlap with the HMD. For the new model, the tests using the HMD dataset provide estimates of internal validity because they are based on the same dataset used for fitting the

¹⁶ By fitting a Kannisto model (i.e., logistic with upper asymptote of one).

model. Since life tables included in the HMD are excluded from the other data sets outlined above, these data provide an opportunity to examine the external validity of the log-quadratic model.

In order to compare the log-quadratic model to the Coale-Demeny and UN model life tables, which have discrete regional families, we create families of the log-quadratic model based on 5 values of the parameter k (-2, -1, 0, 1, and 2). In our tests, we employ two methods for choosing the “best” family from each model life table system given both ${}_5q_0$ and ${}_{45}q_{15}$. For each family included in the model life table system, we choose the “best” level based on either ${}_5q_0$ or ${}_{45}q_{15}$. For the Coale-Demeny and UN model life tables, we interpolate between the discrete levels to produce a life table which accurately matches ${}_5q_0$ or ${}_{45}q_{15}$. Then, we choose the “best” family from a given group of life tables based on which one best reproduces the life table quantity not used to choose level, either ${}_5q_0$ or ${}_{45}q_{15}$. It is obvious from examination of Figure 1 that one will most likely underestimate adult mortality, ${}_{45}q_{15}$, when choosing the best level based on ${}_5q_0$ within the Coale-Demeny model system, especially at low levels of ${}_5q_0$. Where child mortality is low, e_0 is more sensitive to variation in adult mortality. Thus, choosing the level based on ${}_{45}q_{15}$ should produce more accurate estimates in these cases.

In order to make a valid comparison of the models themselves, rather than the datasets that they are fitted to, we have re-estimated the modified logit model using the same HMD dataset used for fitting the log-linear and log-quadratic models. We use this re-estimated model in addition to the original model to compare estimation accuracy in two distinct cases: assuming that either one or two pieces of information are available (either ${}_5q_0$ alone, or ${}_5q_0$ and ${}_{45}q_{15}$ together).

The accuracy of an estimation procedure has been defined in terms of the standard deviation of estimation errors for three key mortality indicators: e_0 , q_0 , and ${}_{45}q_{15}$. The results of comparison tests using the HMD dataset are given in Table 4. The log-quadratic model with 5 k -families produces much better estimates of e_0 than the Coale-Demeny model life tables, the UN model life tables, and a combination of the two regardless of whether ${}_5q_0$ or ${}_{45}q_{15}$ is used to choose level. For the Coale-Demeny and UN model life tables, using ${}_{45}q_{15}$ to choose level and then ${}_5q_0$ to choose “best” family produces more accurate estimates than the inverse procedure as expected.

In the comparison tests using the HMD dataset, the log-quadratic model performs competitively in comparison to the re-estimated modified logit model given either ${}_5q_0$ only or both ${}_5q_0$ and ${}_{45}q_{15}$. As would be expected, the log-quadratic model performs better than the log-linear model and the re-estimated modified logit model has an advantage over the original modified logit model.

The results of the external tests using the HLD, INDEPTH, and WHO collections of life tables are similar to the results of the internal tests using the HMD dataset in that the log-quadratic performs similarly to the modified logit in both its original and re-estimated forms. These results are given in Table 5. The results of tests using the WHO datasets indicate a slight advantage for the original modified logit with regards to estimating male and female e_0 given either ${}_5q_0$ or both ${}_5q_0$ and ${}_{45}q_{15}$, but this advantage is likely due to the model being fit to the data with which

it is being tested. The results of the performance tests using the HLD and INDEPTH data sets indicate a slight advantage for the original modified logit in estimating female e_0 given both ${}_5q_0$ and ${}_{45}q_{15}$. The estimation accuracy for male e_0 among the three models is quite similar in the tests using either the HLD or INDEPTH datasets given either ${}_5q_0$ or ${}_5q_0$ and ${}_{45}q_{15}$. The results of the INDEPTH tests are unusual in that estimation errors for female e_0 are higher than for male e_0 . We will return to issue below when we discuss the external applicability of the model.

Satisfied that the log-quadratic model performs competitively or better than other methods currently in use, we now want to address the internal and external validity of the model. Internal estimation errors for e_0 based on the HMD dataset are plotted in Figure 9. The second and third panels in each column also show error bands, which reflect either one or two times the standard deviation of the corresponding set of errors. Note that the bands are rather narrow when two data inputs are used. Given both ${}_5q_0$ and ${}_{45}q_{15}$, most of the estimates of e_0 are within about a year of the actual value of e_0 . When ${}_5q_0$ is the only input, the error bands are much wider (especially for males). Most of the estimated values of e_0 for females fall within about three years of the actual values while for men the range most of the estimates are within about five years of the actual values.

The results of the external tests using the HLD and WHO collections indicate that the log-quadratic model is applicable in a variety of contexts. The estimation errors for males given only ${}_5q_0$ using either of these external datasets are similar to the estimation errors obtained when using the HMD data (e.g. the standard deviation of the estimation error for e_0 is 2.57 using the HMD data, 2.59 using the HLD data, and 2.57 using the Murray et al. data). For males given both inputs and for females given either one or two inputs, the external tests using HLD and WHO indicate slightly higher estimation errors in comparison to the internal test. Still, the levels are comparable.

The estimation errors observed in the external tests using the INDEPTH data are much higher in comparison to the results obtained using the HMD, HLD, or WHO data. Given the INDEPTH data includes several life tables from African countries with high HIV prevalence, these results would seem to suggest that the log-quadratic model fit to the HMD data does not fully capture the age-pattern of mortality in the context of AIDS. This seems especially true for females since the results indicate higher estimation errors for female e_0 in comparison to male. As suggested earlier, in areas heavily affected by AIDS, the log-quadratic model might be useful in estimating mortality from all other causes. These estimates could be combined with estimates of AIDS mortality derived separately from simulation models.

Discussion

In addition to showing much promise as an estimation tool, the models proposed here can also help to sharpen our understanding of the history of mortality change. Figure 10 illustrates the trajectory of ${}_{45}q_{15}$ vs ${}_5q_0$ for various collections of countries.

As illustrated in Figure 10, most of the countries have followed a fairly regular path over time, in the sense that child and adult mortality did not deviate much from the typical relationship, which

is approximately linear in the chosen scale. This group includes the Nordic countries, Western Europe, and all HMD populations from outside Europe (New Zealand, Australia, Taiwan, Japan, Canada, USA).¹⁷

The bottom panels of Figure 10 show the more unusual historical trajectories of Southern and Eastern Europe, plus the countries of the former Soviet Union. Southern Europe had a somewhat peculiar pattern back in the 1950s or 1960s, especially among women. Bulgarian men (at the southern end of Eastern Europe) also showed a pronounced “South” pattern, as defined by Coale and Demeny (i.e., relatively low adult mortality or, put differently, relatively high child mortality).

However, the dramatic historical pattern traced in recent decades by the former Soviet countries has no comparison (of the East European countries, only Hungary comes close). Russia is the most extreme case, with levels of adult mortality (for both men and women) that far exceed those that would be predicted on the basis of child mortality.

It is clear that the log-quadratic model does not fit all known age patterns of human mortality. It may be possible to improve its precision by adding third-order adjustments (i.e., highly tailored special v_x profiles for certain cases, e.g., war, AIDS). However, those are beyond the scope of this paper. As illustrated here, both the log-linear and the log-quadratic models provide useful first- or second- order approximations in a wide variety of situations.

Conclusion

In addition to generally providing smaller estimation errors, the new method offers other advantages over existing techniques. The proposed model is better suited to the practical needs of mortality estimation, because the two input parameters are both continuous yet the second one is optional. Also, since model parameters are closely related to measures of child and adult mortality, the link between data and estimates is more transparent.

¹⁷ Clearly, this remark pertains only to the period covered for each country by the HMD dataset, which is quite short in some cases.

Appendix

In order to describe the fitting procedure used for the log-linear and log-quadratic models, it is useful to write the two models as follows:

$$\log(m_{xi}) = a_x + b_x h_i + v_x k_i + \varepsilon_{xi} \quad (\text{X})$$

$$\log(m_{xi}) = a_x + b_x h_i + c_x h_i^2 + v_x k_i + \varepsilon_{xi} \quad (\text{X})$$

In this notation, i is an index for a population or an individual life table. In general $i = 1, \dots, n$, and here $n = 616$ (see Table 1). Thus, a_x , b_x , c_x , and v_x are age-specific parameters that are fixed across populations. Only the values of h_i and k_i across time and space, and in all cases $h_i = \log(Q_5)_i$. Given h_i and k_i , the model predicts the value of the log death rate with an error of ε_{xi} .

The two models were fitted to the collection of 616 HMD life tables using a two-step procedure. First, the linear or quadratic portion was fitted by means of OLS regression applied separately to each age group. Second, the $v_x k_i$ term was obtained by computing a singular-value decomposition (SVD) of the resulting residual matrix. In the case of the log-linear model, this can be written as follows:

$$\begin{aligned} \text{SVD}[\ln(m_{xi}) - a_x - b_x \cdot h_i] &= \mathbf{PDQ}^T \\ &= d_1 \mathbf{p}_1 \mathbf{q}_1^T + \dots \end{aligned} \quad (\text{X})$$

where $\mathbf{P} = [\mathbf{p}_1, \mathbf{p}_2, \dots]$, $\mathbf{Q} = [\mathbf{q}_1, \mathbf{q}_2, \dots]$, and \mathbf{D} is a diagonal matrix with elements d_1 , d_2 , etc. Only the first term of the SVD, $d_1 \mathbf{p}_1 \mathbf{q}_1^T$, is used for fitting model (2). The typical age pattern of deviations from the exact log-linear model is depicted by the first left-singular vector; thus, the values of v_x are set equal to the elements of \mathbf{p}_1 .

In some sense the best estimate for k_i in this situation would be derived by multiplying d_1 times the appropriate element of the first right-singular vector, \mathbf{q}_1 . However, as a tool for estimation, we choose k_i to match ${}_{45}q_{15}$ for population i .

[Footnote: After fitting, v_x was set to zero for certain age groups: 0, 1-4, and above 90. It was also set to zero in a few cases (only at older ages) where it was (slightly) negative. See Table 3.]

Notes:

- (1) Life tables by sex are counted only once. Throughout Table 1, we count a maximum of one life table per country-period.
- (2) If the death counts used to construct the life table come from more than one year, we count exposure-to-risk over the full period.
- (3) Data for New Zealand refer to the non-Maori population prior to 1950 and to the full national population after 1950.

Total	--	370	56,837.1

Notes:

- (1) Person-year estimates are based on historical population data for each area. If the death counts used to construct the life table come from more than one year, we count exposure-to-risk over the full period.
- (2) For some areas, life tables represent subpopulations.
- (3) Life tables from the HLD that overlap with those in the HMD or the WHO collection (see Tables 1a and 1b) are not listed here.

Table 2

Correlation coefficients, age-specific death rates vs. probability of dying under age 5 (both in logarithmic scale), Human Mortality Database life tables ($n = 616$)

Age group	Female	Male
0	0.983	0.984
1-4	0.967	0.960
5-9	0.941	0.931
10-14	0.937	0.934
15-19	0.929	0.902
20-24	0.934	0.798
25-29	0.946	0.836
30-34	0.955	0.866
35-39	0.960	0.874
40-44	0.960	0.865
45-49	0.945	0.837
50-54	0.941	0.808
55-59	0.929	0.772
60-64	0.941	0.773
65-69	0.927	0.774
70-74	0.911	0.798
75-79	0.873	0.782
80-84	0.802	0.745
85-89	0.706	0.666
90-94	0.581	0.510
95-99	0.396	0.400
100-104	0.189	0.266
105-109	-0.002	0.146
110+	-0.129	0.058

Note: Table shows correlations between $\log({}_n m_x)$ and $\log(Q_{5i})$.

Table 3Coefficients for two mortality models, estimated using HMD life tables ($n = 616$)

a) Log-linear model

Age	Female			Male		
	a_x	b_x	v_x	a_x	b_x	v_x
0	-0.4168	0.9504	0.0000	-0.3089	0.9720	0.0000
1-4	--	--	--	--	--	--
5-9	-3.5376	1.0838	0.3188	-3.7189	1.0127	0.1959
10-14	-4.1467	0.9686	0.3684	-4.4690	0.8404	0.1904
15-19	-4.0938	0.8365	0.4127	-4.5015	0.5813	0.2338
20-24	-3.8240	0.8543	0.4002	-4.1088	0.5863	0.3176
25-29	-3.7146	0.8440	0.3655	-4.1047	0.5781	0.3704
30-34	-3.7149	0.7764	0.3294	-4.0907	0.5438	0.3848
35-39	-3.7412	0.6844	0.2766	-4.0110	0.4936	0.3749
40-44	-3.7923	0.5750	0.2280	-3.9010	0.4256	0.3458
45-49	-3.8408	0.4616	0.1649	-3.7671	0.3519	0.2938
50-54	-3.6326	0.4124	0.1302	-3.5543	0.2949	0.2423
55-59	-3.3746	0.3762	0.0997	-3.3321	0.2406	0.1847
60-64	-2.9408	0.3719	0.0617	-2.9883	0.2158	0.1465
65-69	-2.5365	0.3508	0.0286	-2.6456	0.1917	0.1093
70-74	-2.0962	0.3260	0.0000	-2.2371	0.1816	0.0778
75-79	-1.7233	0.2816	0.0000	-1.8473	0.1651	0.0456
80-84	-1.4421	0.2167	0.0000	-1.4878	0.1421	0.0252
85-89	-1.1701	0.1588	0.0000	-1.1578	0.1162	0.0015
90-94	-0.9296	0.1098	0.0000	-0.8909	0.0854	0.0000
95-99	-0.7258	0.0651	0.0000	-0.6576	0.0615	0.0000
100-104	-0.5600	0.0294	0.0000	-0.4796	0.0389	0.0000
105-109	-0.4264	0.0045	0.0000	-0.3462	0.0208	0.0000
110+	-0.3349	0.0000	0.0000	-0.2608	0.0000	0.0000

Note: There are no estimated coefficients for ages 1-4 by design. Since Q_5 is an input to the model, ages 1-4 are excluded: it is sufficient to estimate mortality for age 0 and then to derive mortality for ages 1-4 as a residual component of Q_5 .

Table 3 (cont.)

b) Log-quadratic model

Age	Female				Male			
	a_x	b_x	c_x	v_x	a_x	b_x	c_x	v_x

Figure 1

Relationship between child and adult mortality levels (${}_5q_0$ and ${}_{45}q_{15}$), observed data ($n = 616$) and Coale-Demeny model life tables (4 regional families)

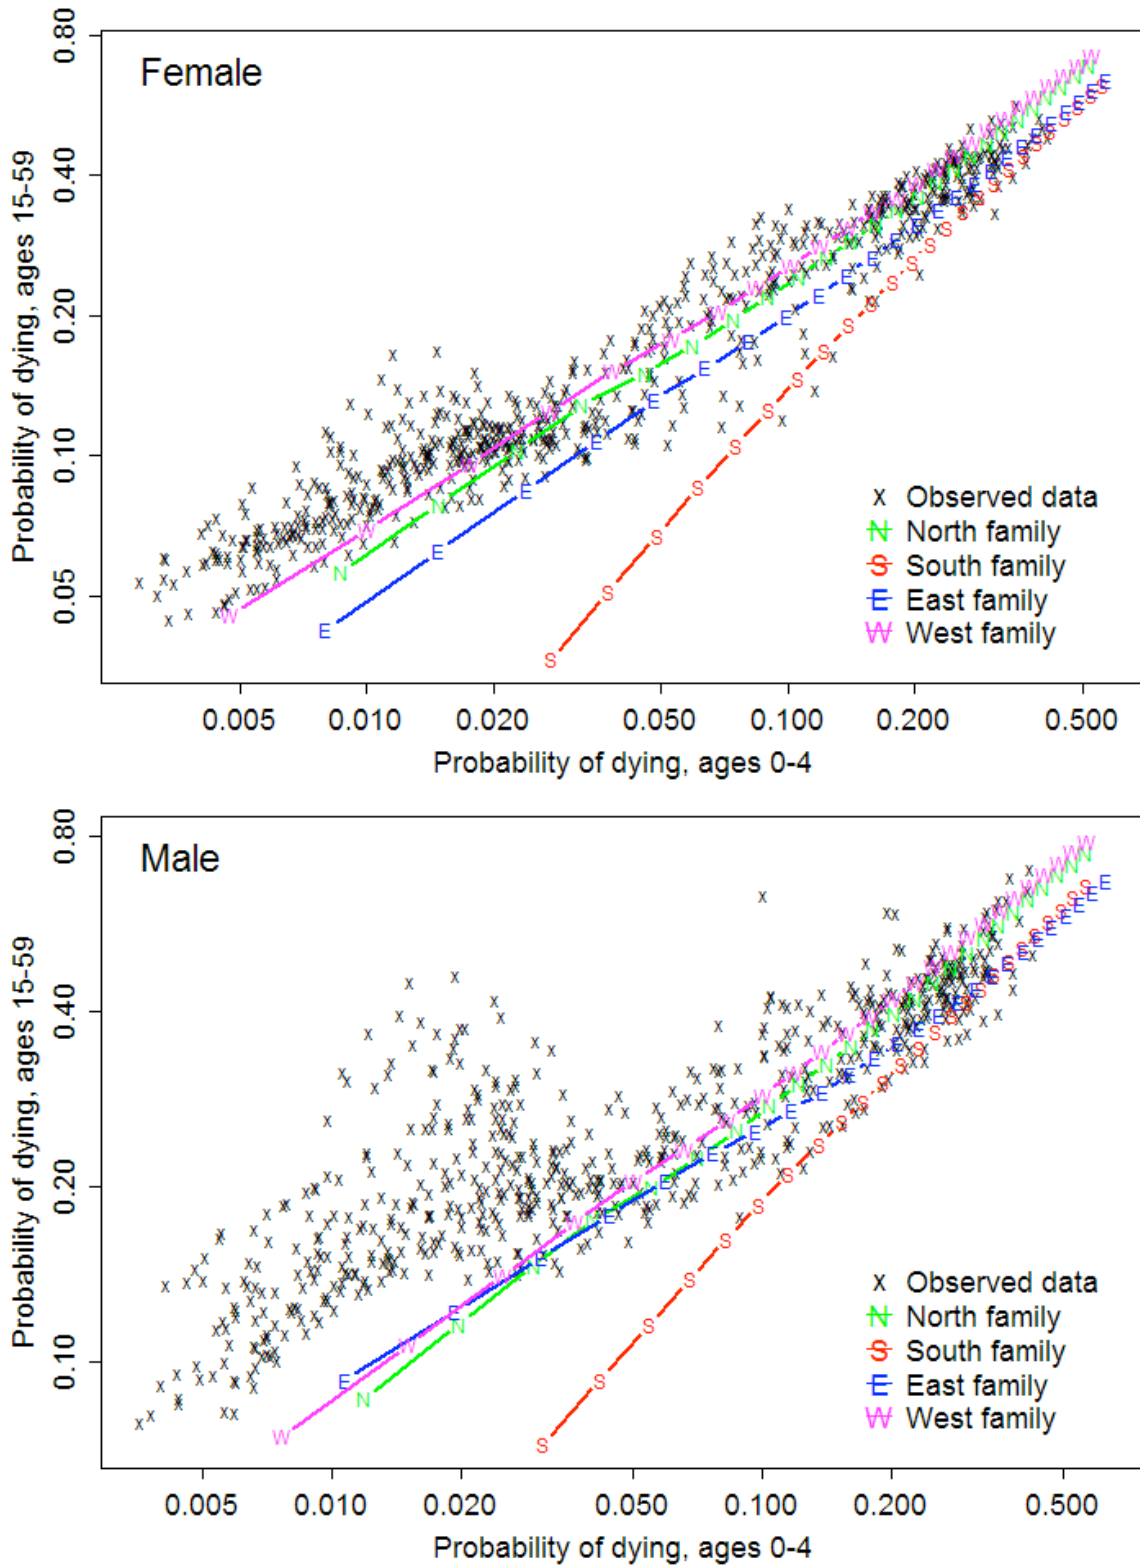

Figure 2
 Age-specific death rates (${}_nM_x$) vs. child mortality (${}_5q_0$),
 log-linear vs. log-quadratic models, total population (sexes combined)

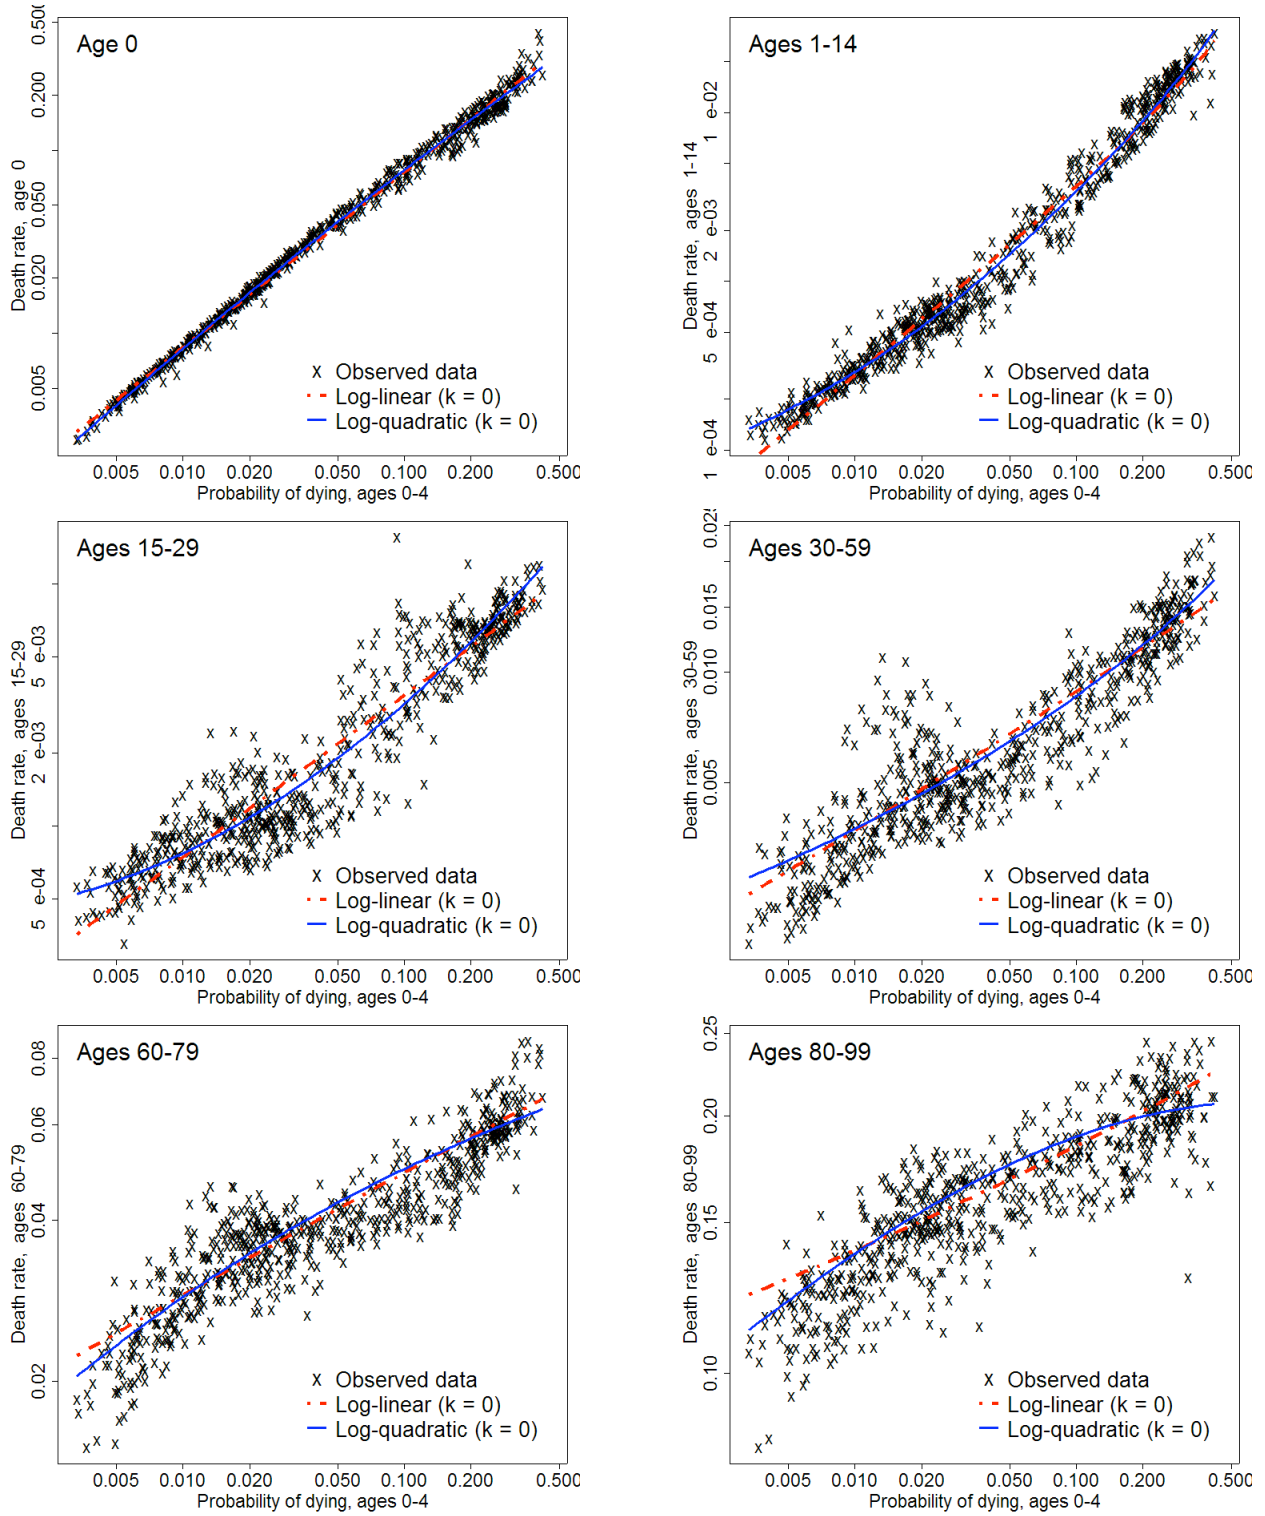

Figure 3

Typical age patterns of mortality implied by the log-quadratic model

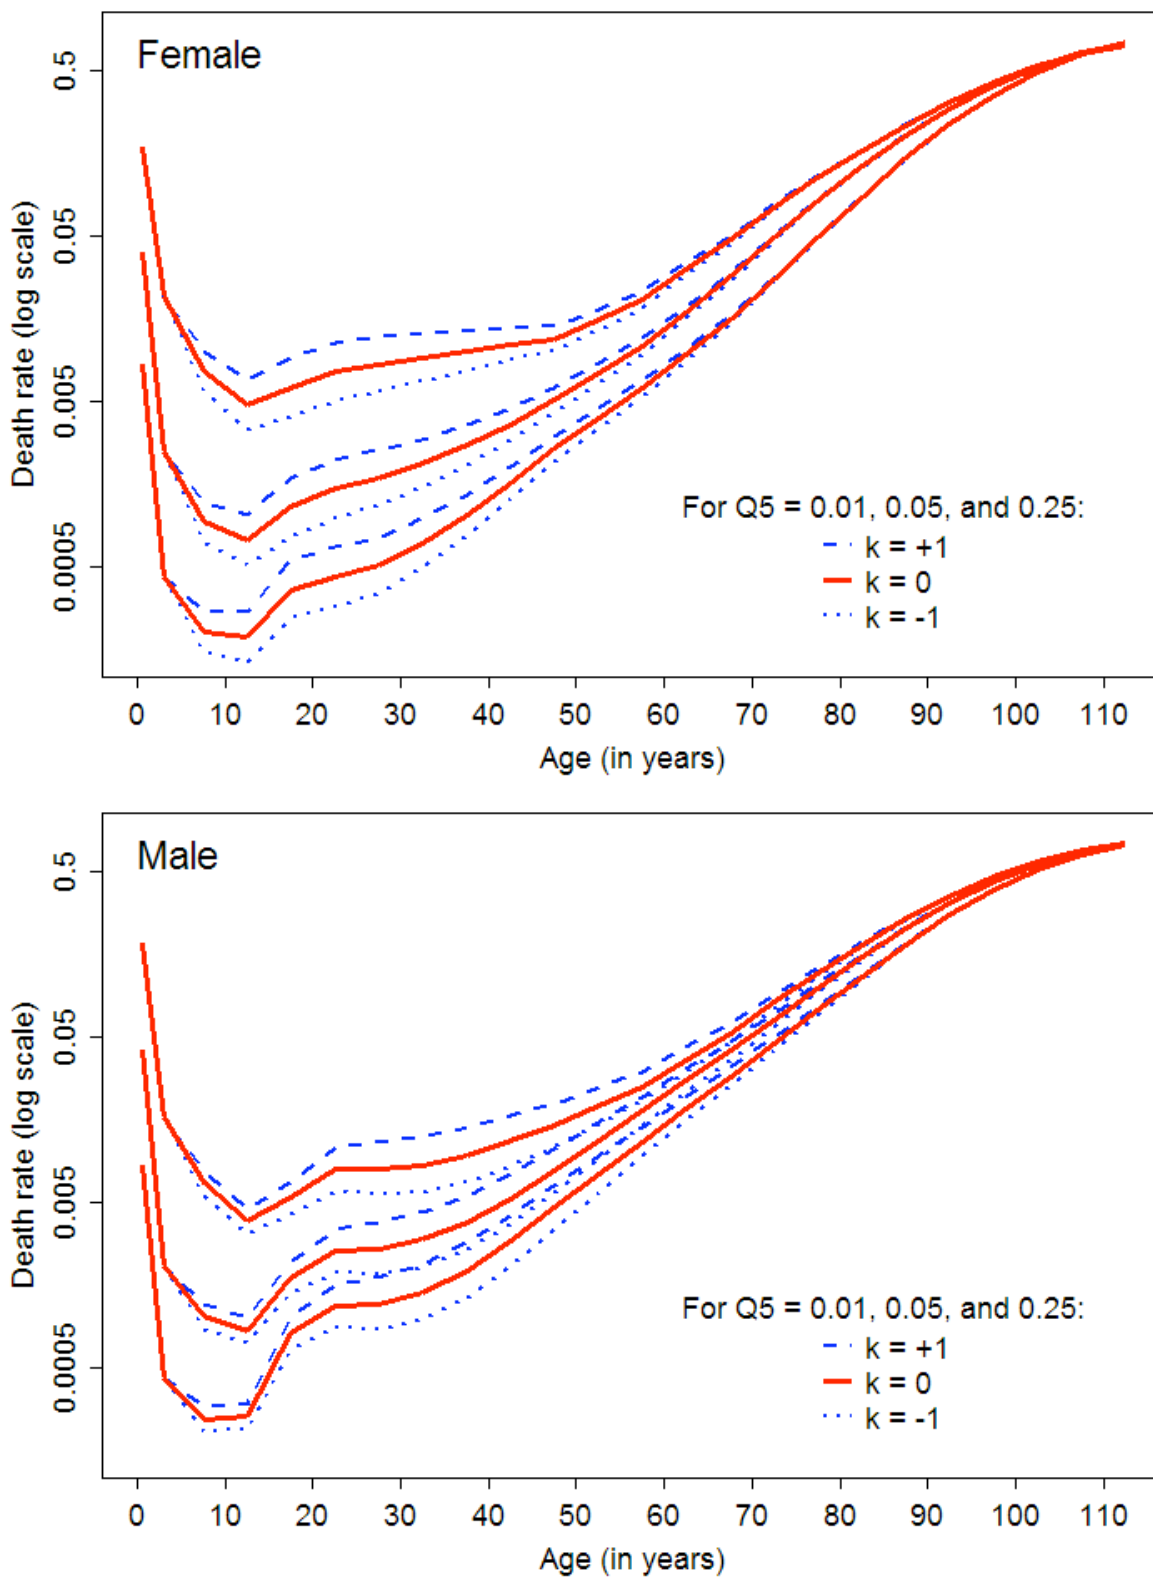

Figure 4

Age patterns of mortality implied by various selections of two input parameters

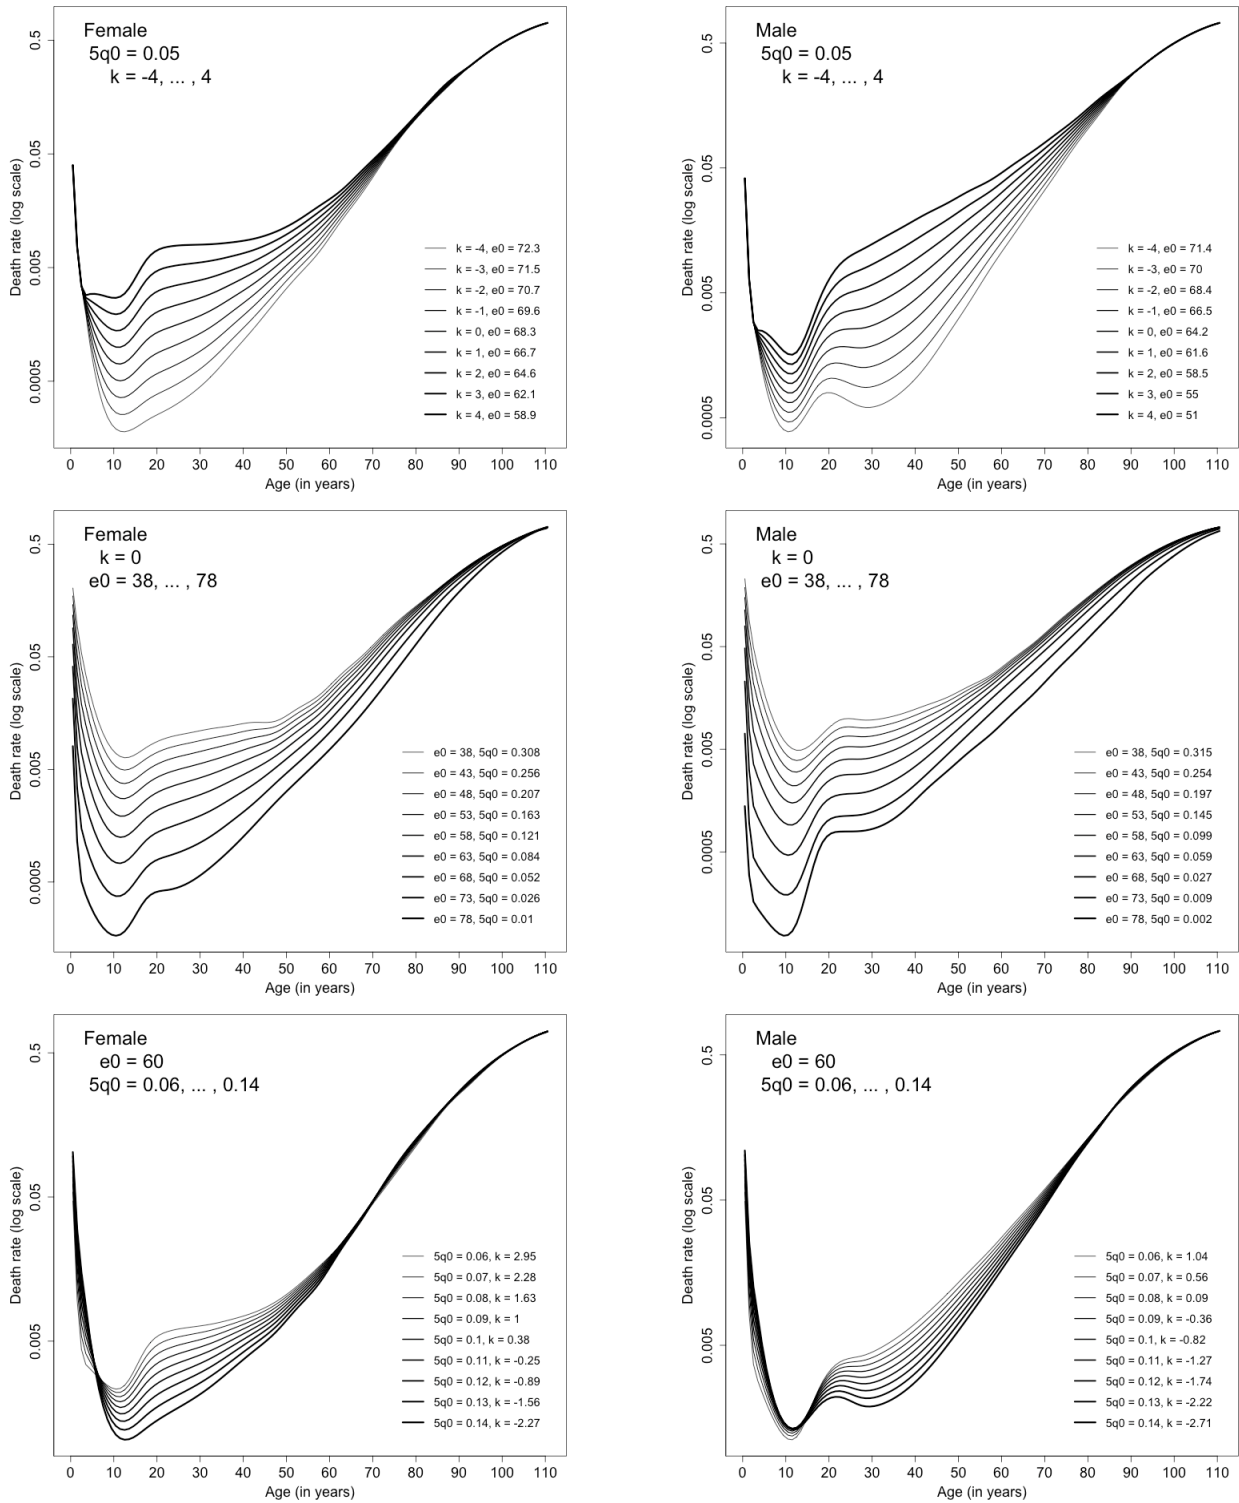

Figure 5

Adult mortality (${}_{45}q_{15}$) vs. child mortality (${}_5q_0$), by sex,
observed data ($n = 616$) and log-quadratic model (for 5 values of k)

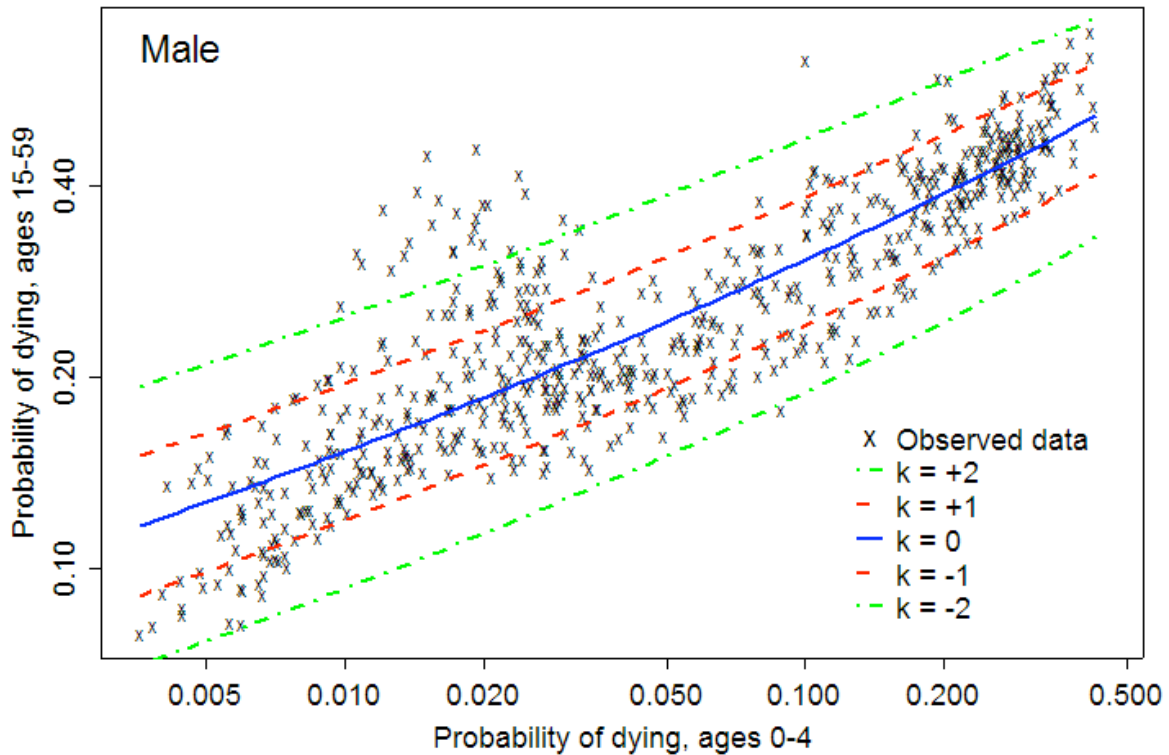

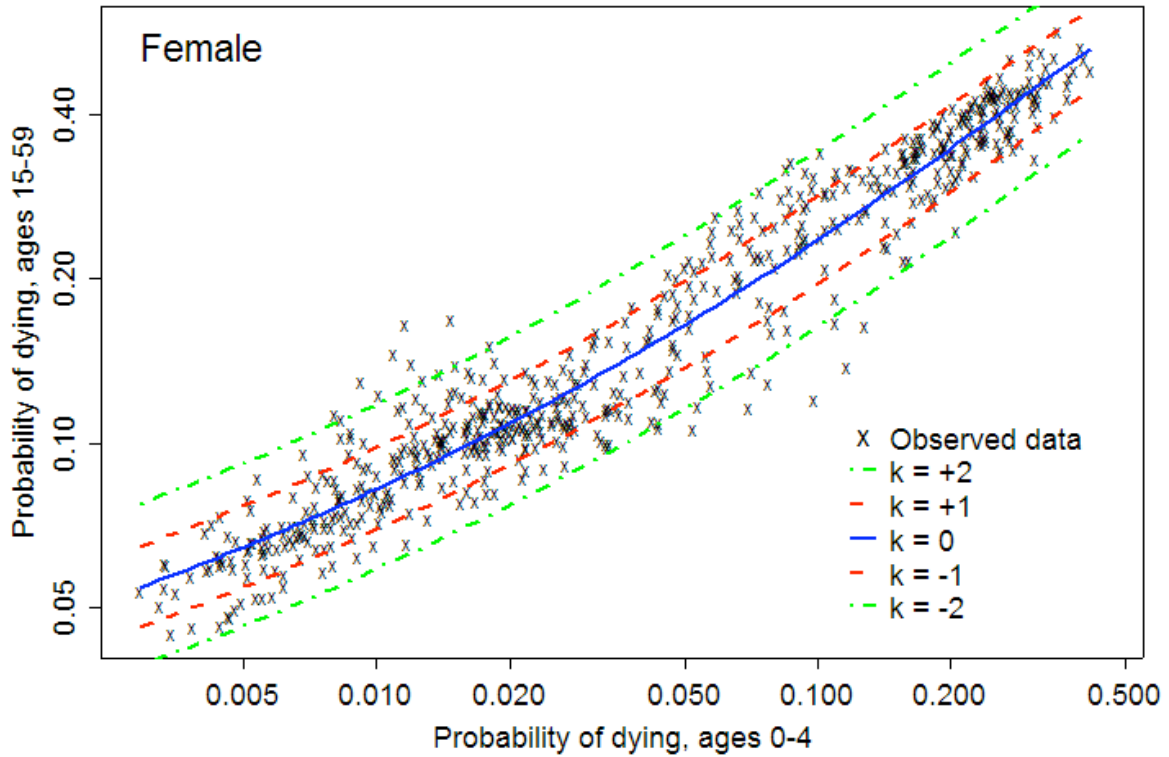

Figure 6

Age-specific death rates (${}_nM_x$) vs. child mortality (${}_5q_0$) for 6 age groups, observed data ($n = 616$) and log-quadratic model (for 5 values of k)

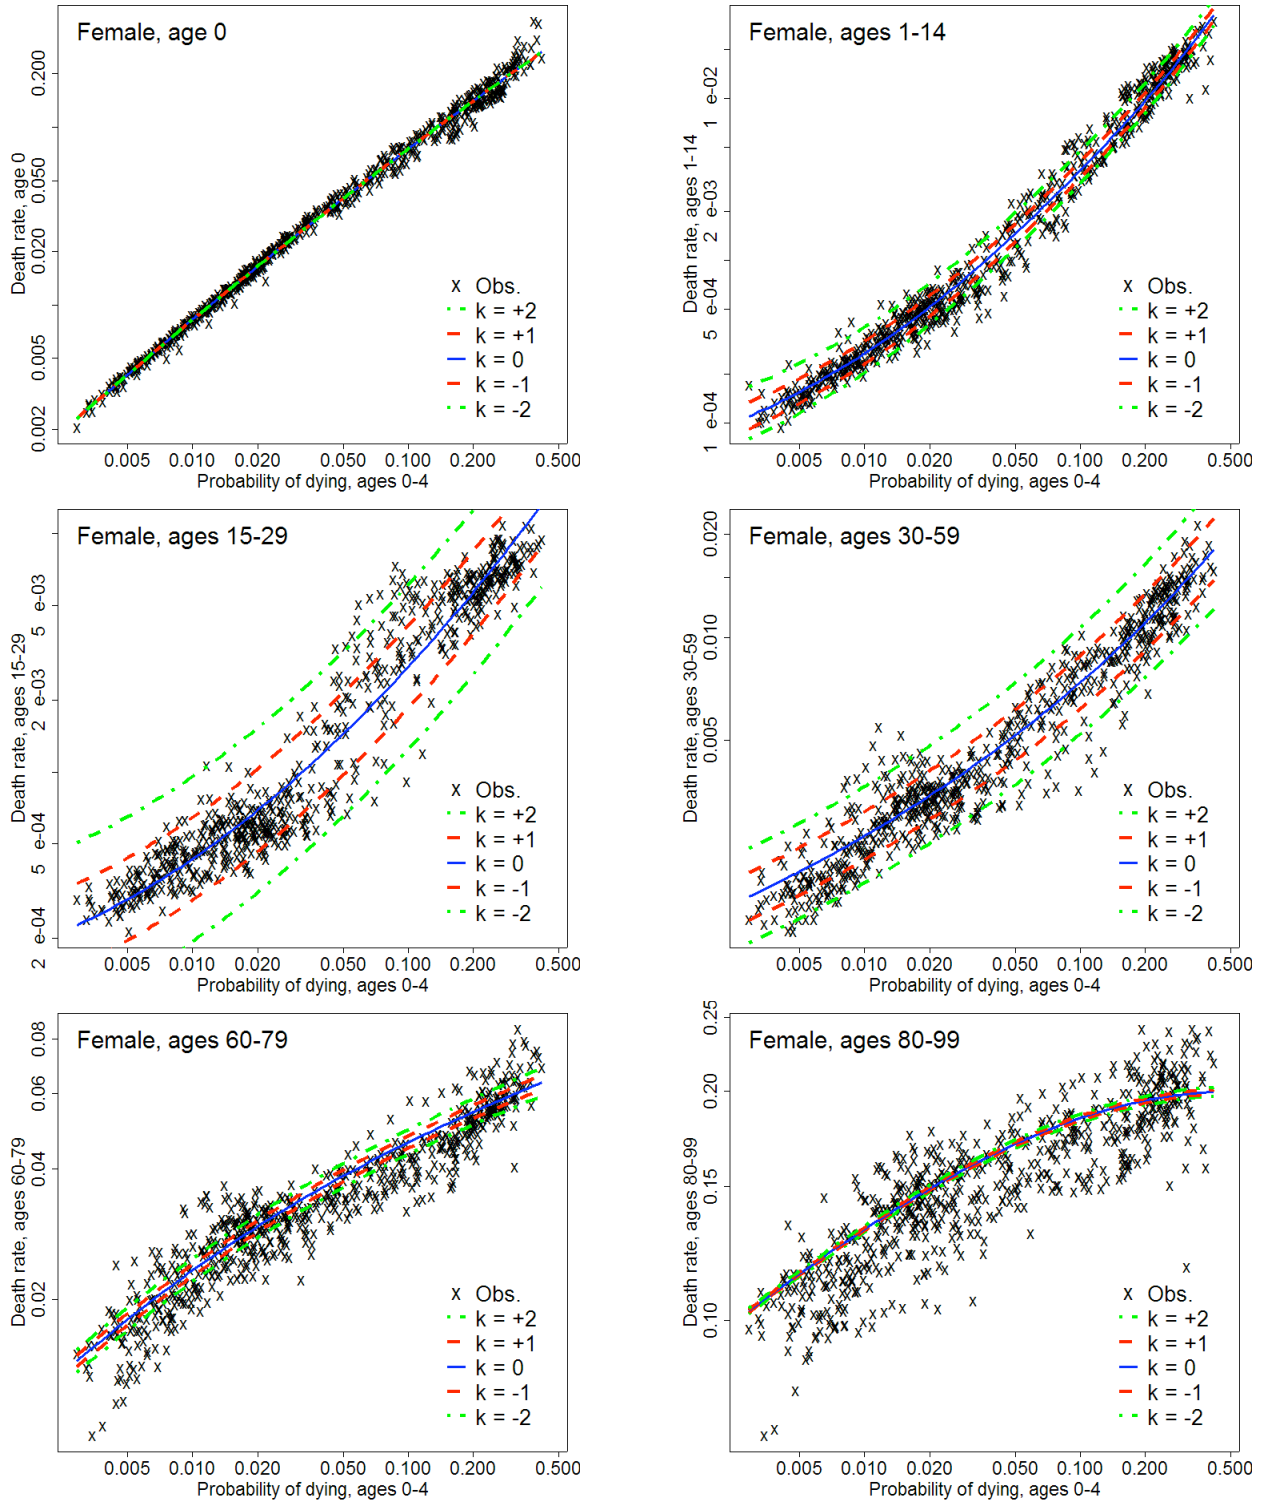

Figure 6 (cont.)

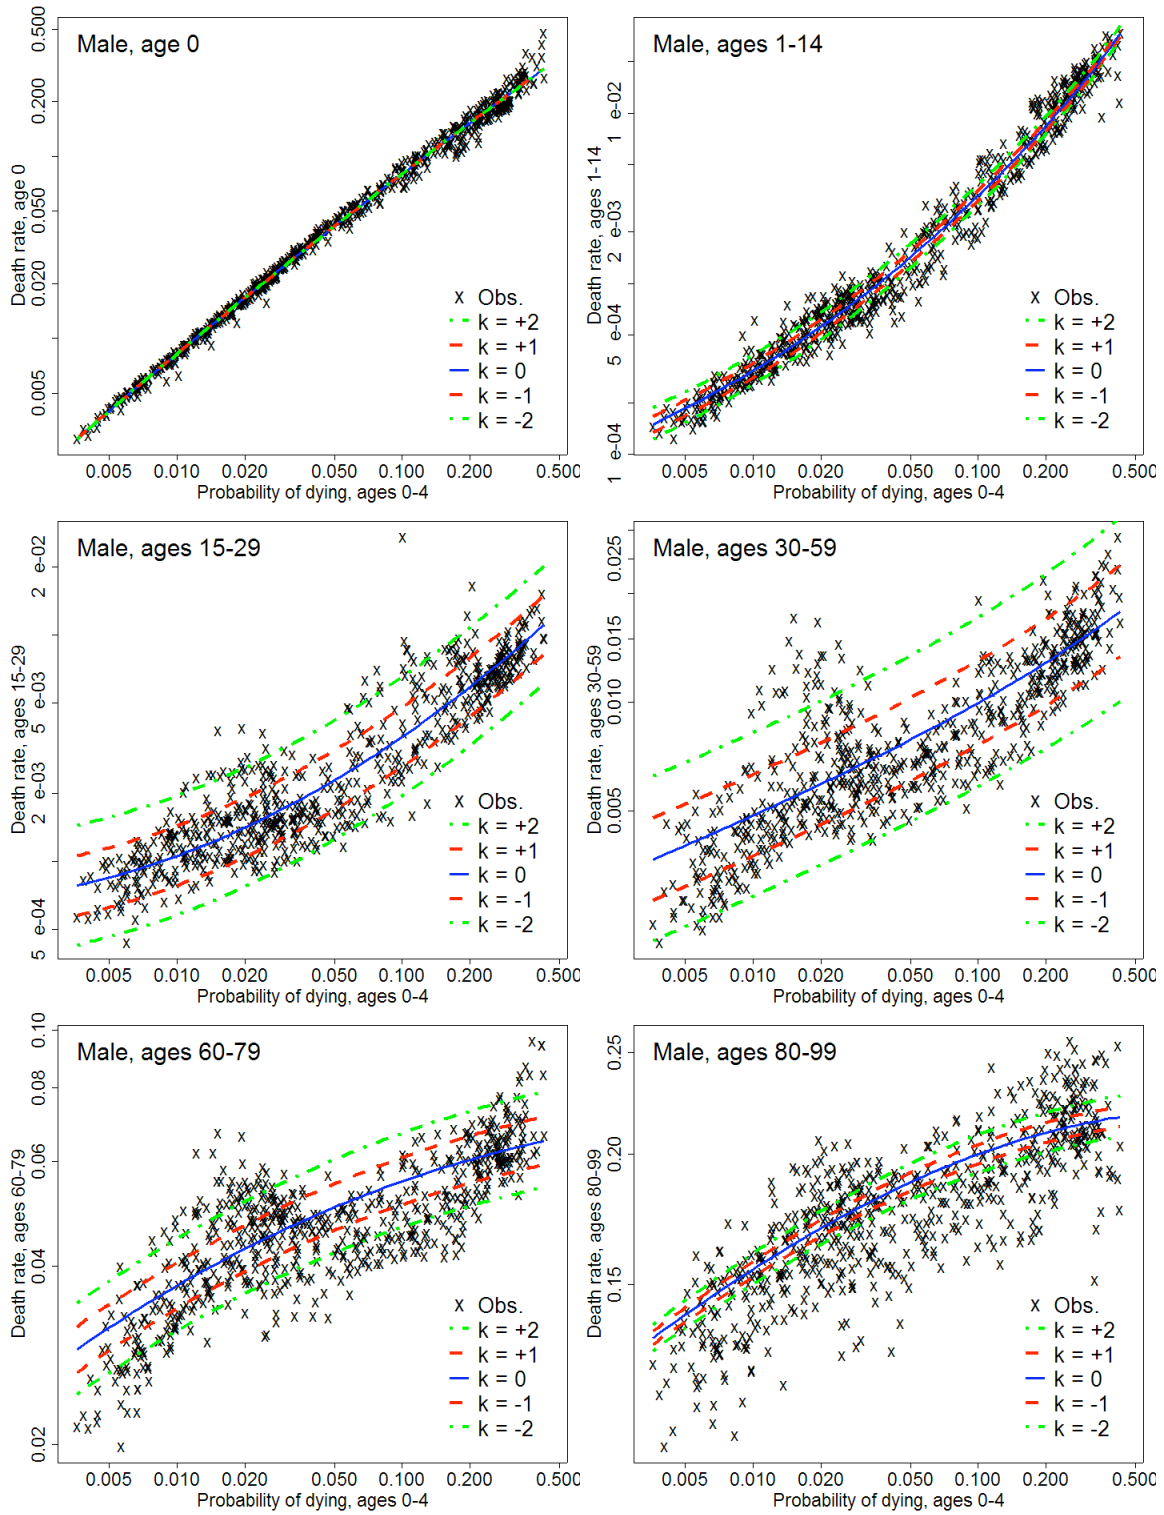

Figure 7
 Six examples of mortality curves derived using
 the log-quadratic model (given ${}_5q_0$ only, or ${}_5q_0$ and ${}_{45}q_{15}$)

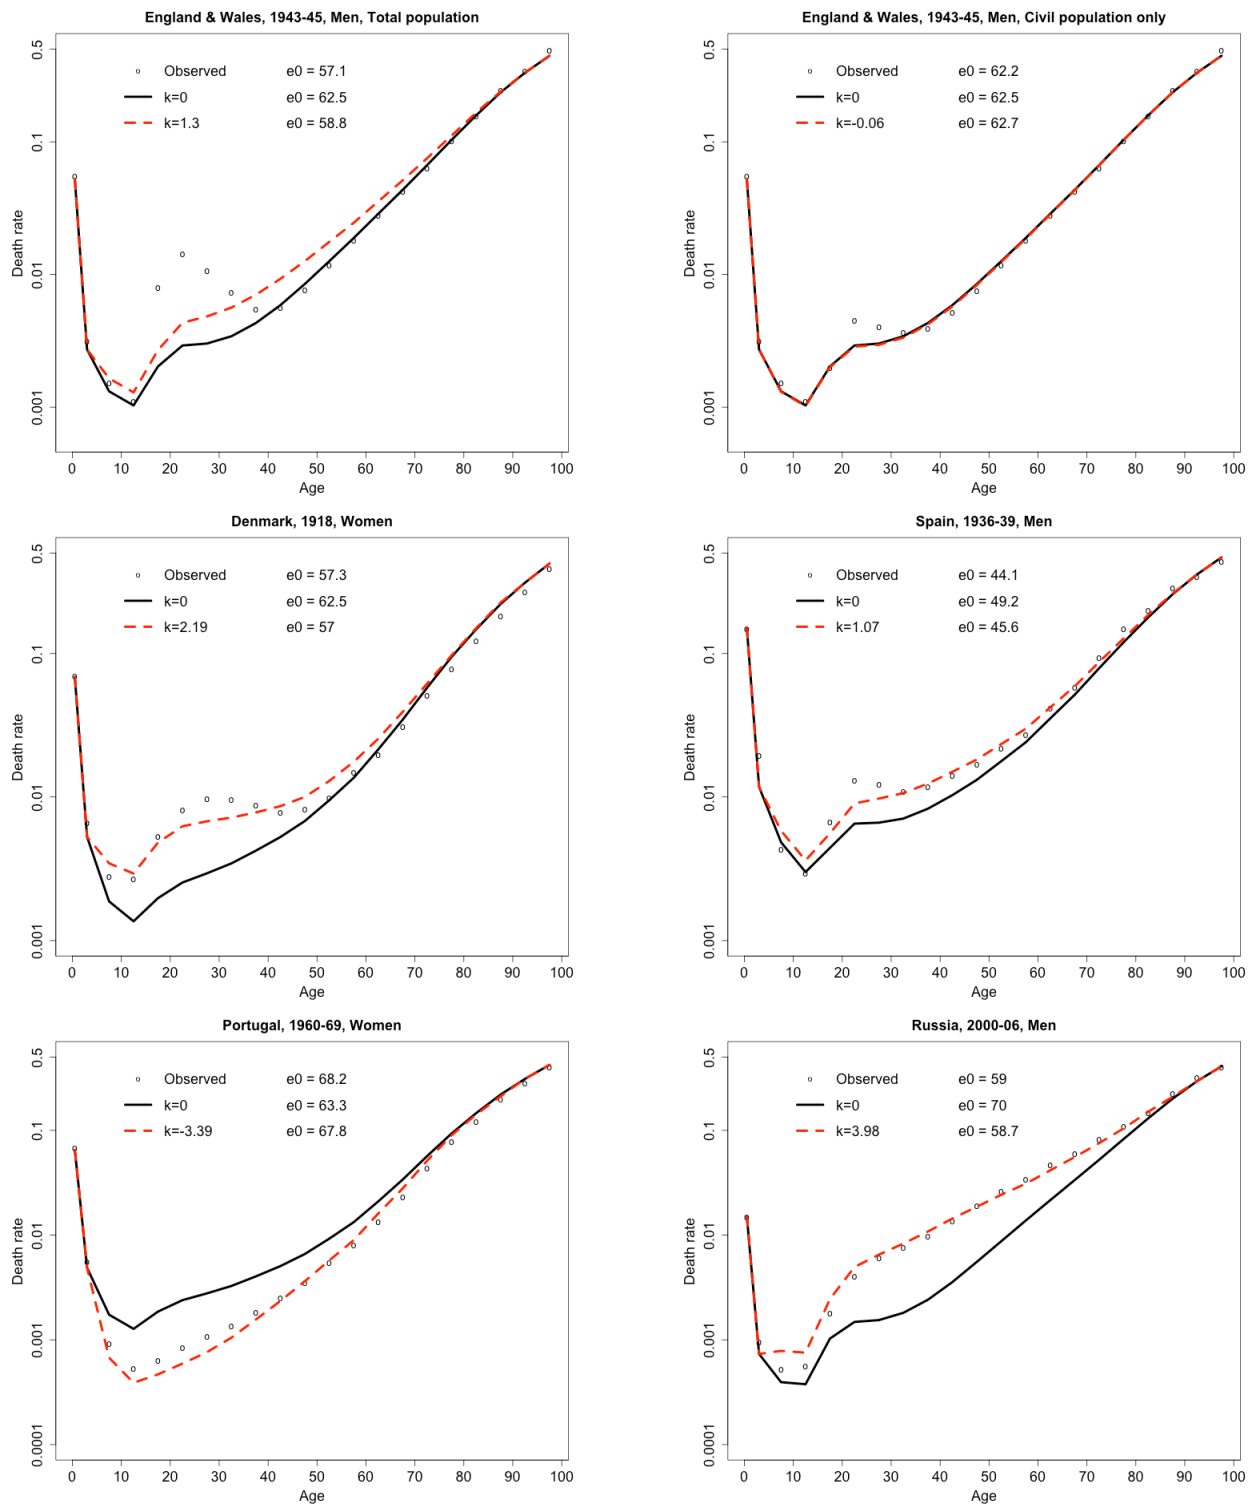

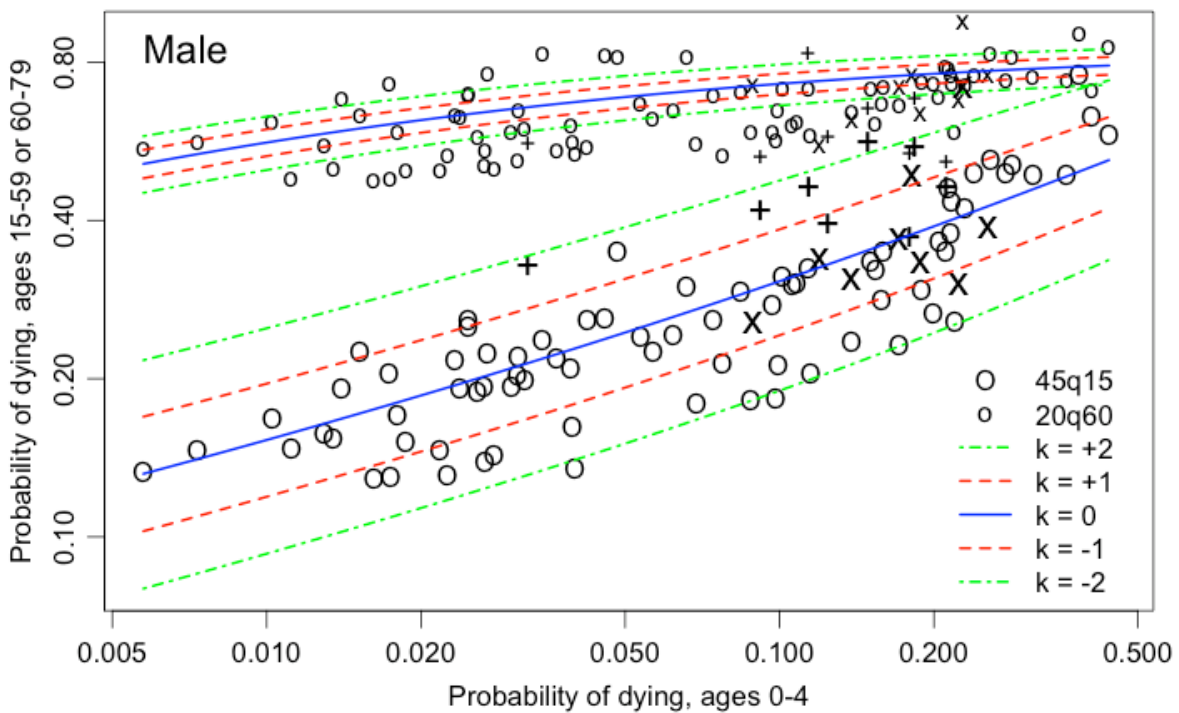

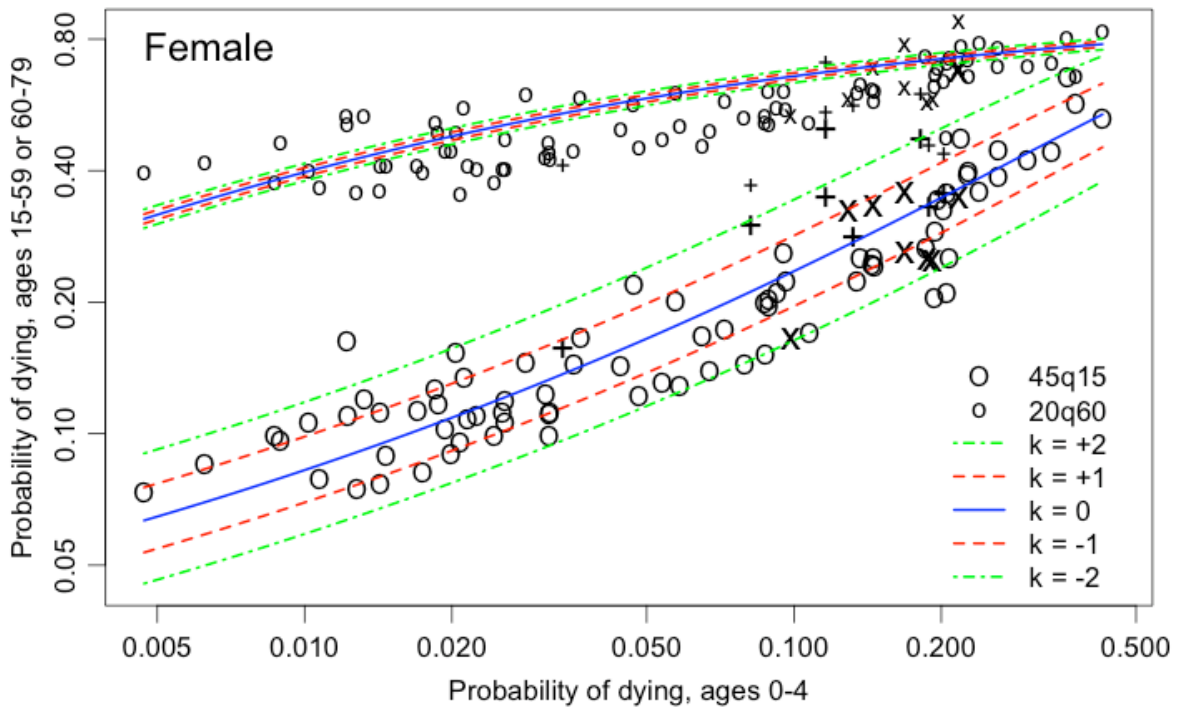

Figure 8

Adult and old-age mortality (${}_{45}q_{15}$ and ${}_{20}q_{60}$) vs. child mortality (${}_5q_0$) for various developing country populations, compared to predictions of the log-quadratic model

○ = WHO-1802 developing country only, x = INDEPTH low HIV, + = INDEPTH high HIV

Figure 9

Estimation errors for life expectancy at birth (estimated minus observed), with error bands (plus/minus 1 or 2 standard deviations), for 1- and 2-dimensional log-quadratic model

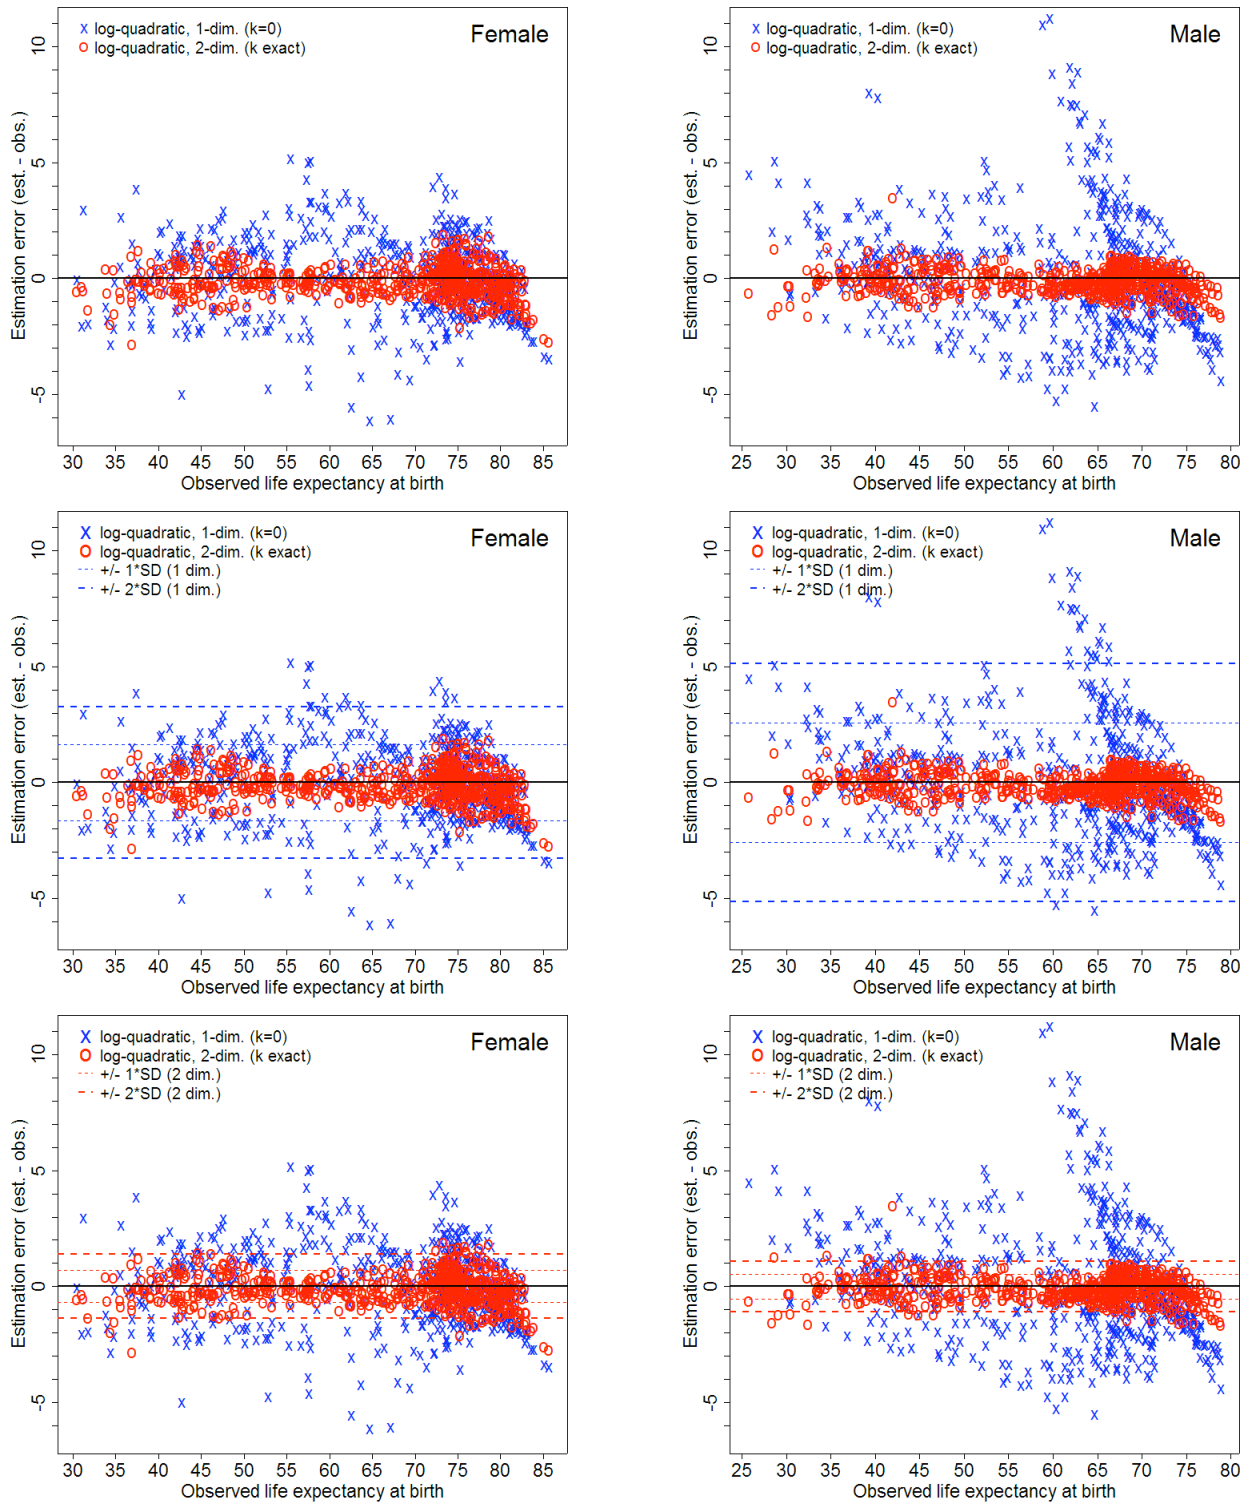

Figure 10
 Adult mortality (${}_{45}q_{15}$) vs. child mortality (${}_5q_0$),
 country patterns plus log-quadratic model (for 5 values of k)
